**(54) WET AGITATING BALL MILL AND METHOD**

(57) A wet agitating ball mill wherein a shaft (5) rotated by a motor is axially hollow at an upper portion thereof to form a discharge port (9) communicating with a slurry discharge port, and has at a lower portion thereof rotors (11). A separator (4) comprises a pair of disks (21) and blades (22) connecting both disks to form an impeller which rotates to impart centrifugal forces to slurry and a medium having entered the separator (4) whereby the medium having a greater specific gravity is scattered radially outward due to the difference in specific gravity and separated from the slurry. The slurry having a smaller specific gravity is discharged through the discharge port (9) of the shaft (5) while having no kinetic energy.

FIG. 2

EP 0 771 591 A1

## Description

The present invention relates to a wet agitating ball mill of friction grinding type, a grinding method by using this mill, and a method of recovering ground product.

## BACKGROUND ART

A wet agitating ball mill of friction grinding type is generally composed of a cylindrical enclosed type stator, a rotor of pin, disk or annular type disposed in the axial center of the stator and to be rotated and driven by the motor, and the mill is filled with medium such as zirconia, glass beads, titanium oxide, steel balls or zirconia silicate, and the raw slurry in a material tank is supplied into the mill through a material pump, and the rotor is rotated and driven to agitate and mix the medium and slurry, thereby grinding the slurry. The ground slurry is discharged out of the mill after separating the medium by the separator, and is returned into the material tank. This operation is repeated, and grinding is promoted. When reaching a desired product particle size, the mill is stopped, and the slurry in the material tank is transferred and collected in a product tank. After stopping the mill, the product slurry left over in the mill remains in the mill, but if it is possible to solidify to disturb next operations, the inside of the mill was cleaned by feeding cleaning water while operating the mill, and the slurry diluted by cleaning water and discharged from the mill was discarded.

The medium used in this type of mill were reduced in diameter as the product grain size became smaller according to the requests of customers, and it was not rare to use medium with diameter of about 0.1 mm. One of the problems that must be solved in the mill for such fine pulverizing is the separation technology for separating the medium efficiently from the slurry. As the separator for separating medium from the slurry, hitherto, the screen and slit machines were used, but in the former screen type, it is extremely difficult to drill innumerable holes smaller than the medium diameter, and if fabricated, the pressure loss is large, and clogging is likely to occur. In the latter slit mechanism, a representative example is composed of a disk fixed on a stator, and a disk to be rotated as being fixed on the shaft and forming a slit not allowing medium to pass against the fixed disk by keeping a specific clearance to the fixed disk, and the medium is separated in the slit between the disks, and the slurry is discharged through the slit, but it is extremely difficult in manufacture to define the slit width at about 0.1 mm, and if manufactured, the medium are likely to be caught in the slit, and the disk is damaged easily. Still more, since the slit width is narrow, there is a limited in the slurry discharge amount, that is, the grinding treating capacity of slurry.

As a separator capable of solving these problems, Japanese Laid-open Patent 4-61635 discloses a separator having two disks disposed parallel at a specific interval on the shaft, and coupling the both disks by a

spiral blade in an impeller form. This separator is designed to apply a centrifugal force to the medium and slurry, and scatter the medium having the greater specific gravity radially outward by making use of difference in specific gravity between the medium and slurry, while discharging the slurry of the smaller specific gravity from a discharge route around the shaft, and therefore since a same centrifugal force acts on the same diameter between the disks, the spacing of the disks can be widened and the treating capacity may be increased, and by widening the spacing of the disks, biting or clogging of medium in the disks can be avoided. Hence the separation performance does not change in the time course, and a stable operation is realized for a long period, and the medium can be separated if the diameter is small, and micro medium can be used, and fine pulverizing is hence possible, but in spite of these benefits, on the other hand, the slurry discharged from the discharge route around the shaft has a kinetic energy given the rotation of the separator, that is, the action of centrifugal force, which means the kinetic energy is released wastefully, and unnecessary power is spent.

This separator is usually made of metal, but considering contamination and wear resistance by metal, it is preferred to use ceramics. In the case of ceramics, it is extremely difficult to fabricate in one body. Manufacturing the disks and blade separately, they can be assembled by adhering with adhesive, but when the raw slurry is organic solvent, the adhesive may be fused to have adverse effects on the quality of product slurry, or the separator may be disassembled into individual parts.

Other problem occurring in the mill for fine pulverizing is inaction of mating ring or loss of function of mechanical seal, in the mechanical seal as shown in Fig. 5 provided for shaft sealing of the shaft bearing portion, as the slurry and medium get in and solidify in the clearance between the lower side of the fitting groove to which the O-ring is fitted and the mating ring.

It is a first object of the invention to present a method of recovering product slurry remaining in the mill after grinding, and it is a second object to present a grinding method capable of grinding efficiently by a mill.

It is a third object of the invention to lessen the power in operation in a mill using the separator of the above impeller type, and it is fourth object to avoid loss of function of mechanical seal by preventing clogging of medium and slurry that may impede the function of mating ring of mechanical seal. It is a fifth object to assemble easily the separator with disks and blades without using adhesive.

## DISCLOSURE OF THE INVENTION

In the invention for achieving the first purpose, a screen is provided in the mill bottom, and after grinding, the product slurry remaining in the mill is discharged and recovered through the screen by injecting compressed air or compressed gas such as N<sub>2</sub> gas from above the mill.

According to the method of the invention, the product slurry remaining in the mill after grinding can be effectively recovered.

In the method of the invention, it is predicted that clogging may occur in the screen during recovery. To solve this problem, various methods may be considered, including a method of rotating and driving the rotor during recovery to agitate in the mill so that the medium may not be collected near the screen, a method of recovering in a long time by decreasing the recovering speed (recovery amount per unit time), and a method of blowing compressed air or compressed gas such as N<sub>2</sub> gas from the opposite side of the screen to prevent clogging of screen by back wash, and when rotating and driving the rotor, it is desired to drive at lower speed than when grinding so as to save power required for rotating the rotor and keep low the temperature rise due to rotor rotation.

In the invention for achieving the second object, the filling rate of medium in the mill is 80 to 90% when grinding.

According to the experiment by the present inventors, the relation between the power kWh required for obtaining 1 kg of product slurry and the medium filling rate in the mill is as shown in Fig. 9, in which the smallest power was required for obtaining product slurry of unit weight at medium filling rate of 80 to 90%. It means that most efficient grinding is achieved when the mill is operated at the medium filling rate of 80 to 90%.

In the mill according to the invention, the separator may be of screen or slit mechanism, but the above impeller type separator is preferred owing to the reason mentioned above. In this case, if the mill is lateral, the medium filling rate cannot be increased. That is, when loading medium into the mill stopping its operation, the filling capacity in the mill is about half, and when the level reaches the discharge route, medium escape from the discharge route. It is hence desired to install the mill vertically, and provide the separator in the upper part of the mill, and when the medium filling rate is set at 80 to 90%, as mentioned above, grinding is done most efficiently, and the separator can be positioned higher than the medium filling level, which is also effective to prevent the medium from being placed on the separator and discharged.

The invention for achieving the third object relates to a wet agitating ball mill comprising a cylindrical separator, a feed port of slurry provided at one end of the stator, a discharge port of slurry provided at other end of the stator, a rotor of pin, disk or annular type for agitating and mixing the medium loaded in the stator and the slurry supplied from the feed port, and a separator of impeller type linked to the discharge port and rotating together with the rotor or rotating independently of the rotor to separate the medium and slurry by the action of centrifugal force and discharge the slurry from the discharge port, wherein the axial center of the shaft for rotating and driving the separator is a hollow discharge port communicating with the discharge port.

According to the mill of the invention, the slurry from which medium is separated by the separator is discharged through the axial center of the shaft, but since the centrifugal force does not act on the axial center, the slurry is discharged in a state having no kinetic energy. That is, kinetic energy is not discharged wastefully, and wasteful power consumption is avoided.

The mill of the invention may be lateral, but the vertical position is preferred because of the above reason, that is, to increase the medium filling rate, and the discharge port is provided at the mill upper end. The separator is also preferred to be installed higher than the medium filling level.

When the discharge port is provided at the mill upper end, the feed port is provided in the mill bottom. In a preferred mode, the feed port is composed of a valve seat, and a valve body of V-form, trapezoid or cone fitted elevatably to the valve seat and contacting linearly with the edge of the valve seat, and by forming an annular slit so as not to allow to pass medium between the edge of the valve seat and the valve body of V-form, trapezoid or cone, the raw slurry is fed but falling of medium can be prevented. Moreover by lifting the valve body, it is possible to expand the slit to discharge medium, or by lowering the valve body, it is possible to close the slit and shut the mill tightly. Moreover, since the slit is formed of the valve body and edge of valve seat, coarse particles in the raw slurry hardly get in, and if getting in, they pass through upward or downward, and hardly clog.

Moreover, by vibrating the valve body vertically by vibrating means, coarse particles caught in the slit may be drawn out of the slit, and biting itself occurs hardly. Still more, as shearing force is added to the raw slurry by vibration of valve body, the viscosity drops, thereby increasing the raw slurry passing amount into the slit, that is, the feed rate. The vibrating means for vibrating the valve body includes mechanical means such as vibrator, and means of varying the pressure of compressed air acting on the piston which is integrated with the valve body, such as reciprocating compressor, and electromagnetic changeover valve for changing over suction and discharge of compressed air.

The mill of the invention is further preferred to be provided with a screen for separating the medium and a take-out port of product slurry in the bottom as mentioned above, so that the product slurry remaining in the mill after grinding may be taken out.

The invention for achieving the fourth object relates to a vertical type wet agitating ball mill comprising a cylindrical vertical stator, a feed port of product slurry provided in the bottom of the stator, a discharge port of slurry provided at the upper end of the stator, a shaft pivoted on the upper end of the stator and rotated and driven by driving means such as motor, a rotor of pin, disk or annular type fixed on the shaft for agitating and mixing the medium loaded in the stator and the slurry supplied from the feed port, a separator disposed near the discharge port for separating medium from the

slurry, and a mechanical seal provided in the bearing unit for supporting the shaft at the stator upper end, wherein a taper notch expanding downward is formed at the lower side of an annular groove to which an O-ring contacting with the mating ring of the mechanical seal is fitted.

According to the mill of the invention, the mechanical seal is provided in the axial center where the medium and slurry have almost no kinetic energy, and at the upper end of the stator above their liquid levels, so that invasion of medium or slurry between the mating ring of the mechanical seal and lower side of O-ring fitting groove can be substantially decreased. Moreover, since the lower side of the annular groove to which the O-ring is fitted is expanded downward through the notch and the clearance is widened, clogging due to invasion and solidification of slurry or medium hardly occurs, the mating ring follows up the seal ring smoothly, and the function of the mechanical seal is maintained. Incidentally, the lower side of the fitting groove to which the O-ring is fitted has a V-form section, and the entire structure is not thin wall, and the strength is not sacrificed, and the holding function of the O-ring is not spoiled.

The invention for achieving the fifth object relates to a wet agitating ball mill comprising a cylindrical stator, a feed port of slurry provided at one end of the stator, a discharge port of slurry provided at other end of the stator, a rotor of pin, disk or annular type for agitating and mixing the medium loaded in the stator and the slurry supplied from the feed port, and a separator of impeller type linked to the discharge port and rotating together with the rotor or rotating independently of the rotor to separate the medium and slurry by the action of centrifugal force and discharge the slurry from the discharge port, wherein the separator is composed of two disks having a fitting groove of a blade in the confronting inner sides, a blade interposed between the disks by fitting to the fitting groove, and support means for supposing the disks having the blade placed therein from both sides, and in a preferred form, the support means is composed of a step of the shaft forming a stepped shaft, and cylindrical pressing means for pressing the disks by fitting to the shaft, and the disks placing the blade therein is held and supported from both sides by the step of the shaft and pressing means.

#### BRIEF DESCRIPTION OF THE DRAWINGS

Fig. 1 is a schematic diagram of raw slurry grinding process cycle having a wet agitating ball mill of the invention.

Fig. 2 is a longitudinal sectional view for a wet agitating ball mill of the invention.

Fig. 3 is a longitudinal sectional view of a feed port when feeding raw slurry.

Fig. 5 is a longitudinal sectional view of the feed port when discharging medium.

Fig. 6 is an essential magnified longitudinal sectional view of mechanical seal used in a wet agitating

ball mill.

Fig. 7 is a longitudinal sectional view of other example of a wet agitating ball mill of the invention.

Fig. 8 is a lateral sectional view of a separator of the wet agitating ball mill shown in Fig. 7.

Fig. 9 is a diagram showing the relationship of medium filling rate and mill power basic unit.

#### BEST FORMS OF CARRYING OUT THE INVENTION

In Fig. 1, raw slurry discharged from a material tank 1 storing slurry by a material pump 2 is supplied into a vertical type wet agitating ball mill 3 of friction grinding type, and is agitated and ground together with medium in the mill 3, and is discharged through the axial center of a shaft 5 after separating the medium by a separator 4, and returns to the tank 1, so that it may be ground cyclically in this route.

The mill 3, as specifically shown in Fig. 2, comprises a stator 7 of vertical cylindrical form including a jacket 6 for passing cooling water for cooling the mill, a shaft 5 pivoted rotatably above the stator at the axial center of the stator 7, having a mechanical seal as shown in Fig. 6 in the bearing unit, and forming a hollow discharge route 9 in the axial center of the upper side, a rotor 11 of pin or disk form projecting in the radial direction at the lower end of the shaft, a pulley 14 affixed above the shaft to be connected with belt to a pulley 13 of a motor 12 shown in Fig. 1, a rotary joint 15 mounted at the opening end of the shaft upper end, a separator 5 for separating the medium affixed on the shaft 5 near the upper part in the stator 7, a feed port 16 of raw slurry provided opposite to the shaft end of the shaft 5 in the stator bottom, and a screen 18 for separating the medium, mounted on a grating shaped screen support 17 installed at a product slurry take-out port 19 provided at an eccentric position of the stator bottom.

The separator 4 comprises a pair of disks 21 affixed at a specific spacing on the shaft 5, and a blade 22 for linking the both disks 21, thereby forming an impeller, and rotating together with the shaft 5, centrifugal force is applied to the medium and slurry having entered in between the disks, and the medium is scattered radially outward by the difference in specific gravity, while the slurry is discharged through the discharge route 9 at the axial center of the shaft 5.

The feed port 16 of raw slurry comprises, as specifically shown in Fig. 3, a valve seat 24 formed in the stator bottom, a valve body 25 of inverted trapezoidal form elevatably fitting to the valve seat 24, a cylindrical body 26 with a bottom forming a guide port 27 of raw slurry, projecting downward from the stator bottom, a cylindrical body 28 with a bottom forming a guide port 29 of air, projecting downward from the cylindrical body 26, a piston 31 elevatably fitted to the cylindrical body 28, a rod 32 for linking the piston 31 and valve body 25, a spring 33 mounted on the piston in the cylindrical body 28 for pushing down the piston 31 to thrust the valve body 25 usually downward, and a nut 34 twisted into the rod end

projecting from the cylindrical body 28 and mounted so as to be adjustable in position, and when the valve body 25 is pushed up by supply of raw slurry, an annular slit is formed against the valve seat 24, so that the raw slurry can be supplied into the mill, and the slit width can be adjusted by twisting or loosening the nut 34, and when feeding the material, if the nut 35 hits against the cylindrical body 28 and is expanded to the maximum limit, the width is set so that medium cannot pass through. When feeding the material, the valve body 25 ascends by resisting the pressure in the mill and action of the spring 33 by the feed pressure of the raw slurry fed into the cylindrical body 26, and a slit is formed against the valve seat 24, but the feed pressure of the raw slurry is set so that the width of the slit formed by the supply of raw slurry may be slightly smaller than the maximum slit width defined by the nut 34, and therefore a certain allowance is kept between the nut 34 and cylindrical body 28.

Coarse particles are contained in the raw slurry supplied into the mill through the slit formed between the valve seat 24 and valve body 25, and they may be predicted to be caught between the valve seat and valve body to clog, if clogged by biting, the feed pressure is raised so as to lift the valve body 25 once to the maximum limit to extend the slit width to maximum. As a result, caught coarse particles flow out and clogging is cleared. When clogging is cleared, the feed pressure is lower, and the valve body 25 descends.

To clear clogging in the slit, moreover in the illustrated example, compressed air is supplied from a compressed air source (not shown) into the cylindrical body 28 from the guide port 29 through regulator 23 and electromagnetic changeover valve 30, and by changing over the electromagnetic changeover valve 30 by turning on and off repeatedly in a short period, compressed air is supplied intermittently, and the valve body 25 repeats vertical motion to ascend to the upper limit in a short period, so that biting can be cleared.

The vibration of the valve body 25 may be done always, or when lots of coarse particles are contained in the raw slurry, or the vibration may occur in cooperation when the feed pressure of raw slurry is raised due to clogging.

After grinding, when taking out the agitated medium together with the product slurry or after discharging the product slurry, as shown in Fig. 4, the mounting position of the nut 34 is lowered. Then the electromagnetic changeover valve 30 is changed over to ON position. As a result, the compressed air introduced from the guide port 29 causes to lift the valve body 25 above the edge of the valve seat 24.

In the mechanical seal, as specifically shown in Fig. 5 and Fig. 6, a mating ring 36 at the stator side is press-fitted to a seal ring 35 fixed to the shaft 5 by the action of a spring 37, and sealing of the stator 7 and mating ring 36 is achieved by an O-ring 39 fitted in a fitting groove 38 at the stator side, and in Fig. 6, a taper notch 40 expanding downward is cut at the lower end of the O-

ring fitting groove 38, and the length  $a$  of the minimum clearance portion between the lower side of the fitting groove 38 and mating ring 36 is narrower than in Fig. 5, thereby preventing invasion and solidification of medium and slurry, impedance of motion of the mating ring 36, and loss of sealing of the seal ring 35.

In this embodiment, the rotor 11 and separator 4 are fixed on the same shaft 5, but in other embodiment, they are fixed on different shafts disposed coaxially and are rotated and driven independently. In the above embodiment where the rotor and separator are mounted on the same shaft, only one driving device is needed and the structure is simple, and in the latter embodiment where the rotor and shaft are mounted on different shafts and are rotated and driven by individual driving devices, on the other hand, the rotor and separator can be rotated and driven at optimum rotating speeds, individually.

In the ball mill shown in Fig. 7, a shaft 43 is a stepped shaft, a separator 44 is inserted from the lower end of the shaft, a spacer 45 and a rotor 46 of disk or pin form are inserted alternately, a stopper 47 is fixed to the lower end of the shaft by a screw 48, and after the separator 44, spacer 45, and rotor 46 are inserted into the shaft 43, they are fixed by pinching with the step 43a of the shaft 43 and the stopper 47, and the separator 44 comprises, as shown in Fig. 8, a pair of disks 52 forming blade fitting grooves 51 on the inside confronting sides, a blade 53 interposed between the disks and fitting in the blade fitting grooves 51, and an annular spacer 56 forming a hole 55 communicating with a discharge route 54, maintaining the both disks 52 at a specific spacing, thereby composing an impeller.

A grinding method of raw slurry by employing the apparatus shown in Fig. 1 is described below.

The stator 7 in the ball mill 3 is filled with medium by 80 to 90% of the inner volume of the stator, the valves 58, 59 and 60 are closed, and valves 61 and 52 are opened, and first the motor 12 is driven, and then the material pump 2 is driven. When the motor 12 is driven, the rotor 11 and separator 4 are rotated, and when the material pump 2 is driven, the raw slurry in the material tank 1 is sent into the guide port 27 of the feed port 16 at specific feed rate, and is supplied into the mill through the slit formed between the edge of the valve seat 24 and the valve body 25.

By rotation of the motor 11, the raw slurry and medium in the mill are agitated and mixed, and the slurry is ground, and by rotation of the separator 4, the medium and slurry having entered into the separator are separated by the difference in specific gravity, and the medium of greater specific gravity is scattered radially outward, while the slurry of the smaller specific gravity is discharged through the discharge route 9 formed in the axial center of the shaft 5, and is returned to the material tank 1.

In this method, the motor 12 is driven prior to driving of the material pump 2 because medium is discharged when raw slurry is supplied before the

separating action by the separator.

The slurry returned to the material tank 1 is supplied again into the mill by the material pump 2, and repeats the same cycle and ground progressively. When ground to a certain extent, the particle size of the slurry is measured occasionally, and when reaching a desired particle size, once the material pump is stopped, and then the motor 12 is stopped to stop operation of the mill 3, thereby finishing the grinding process. Later, the valves 58 and 59 are opened, and the valves 61 and 62 are closed, and the material pump and motor 12 are started again, and then the valve 60 is opened. As a result, the product slurry in the material tank 1 is discharged by the material pump 2, and is sent into a product tank 63, while the product slurry in the mill is agitated by rotation of the rotor 7, and is pushed out through the screen 18 by compressed air or  $N_2$  gas passed through the valve 60 and discharge route 9, or fed into the mill from above the mill, and is sent into the product tank 63. In this way, the product slurry in the material tank and mill 3 is recovered in the product tank 63. Meanwhile, rotation of the rotor 7 during product recovery is intended to prevent clogging in the screen 18 by mixing so that the medium may not sediment in the mill to be collected in the mill lower layer, and proper compressed air or  $N_2$  gas for clearing clogging is introduced from the take-out port, and the screen 18 is back washed.

#### EXPERIMENT

In Fig. 1, using a mill with the inside diameter of the stator 7 of 80 mm $\phi$ , inner volume of 1 liter, diameter of separator 4 of 60 mm $\phi$ , and interval of disks 21 of the separator 4 of 5 mm, the mill was filled with zirconia  $ZrO_2$  (specific gravity 6.0) of particle size of 0.1 mm as medium by 50%, and slurry of calcium carbonate  $CaCO_3$  with mean particle size of 6.6  $\mu m$  and water was supplied from the material tank 1 into the feed port 16. The mill 3 was operated at constant rotor rotating speed (peripheral speed at the rotor leading end of 8 m/sec), and the slurry was ground cyclically. When the mean diameter reached the target of 1.0  $\mu m$ , the mill operation was stopped, and product slurry was obtained. The experiment was conducted by varying the medium filling rate from 50 to 95%, and from the required power kWh, the power basic unit for obtaining 1 kg of product slurry was determined. The result is shown in Fig. 9. As clear from Fig. 9, the power basic unit decreased at the medium filling rate of 80 to 90%, and the most efficient grinding was confirmed in this range.

#### Claims

1. A recovery method of product slurry in a method of grinding raw slurry by a wet agitating ball mill comprising a stator to be filled with medium, a rotor affixed to a shaft rotated and driven by a driving device such as motor, a feed port of raw slurry provided in the stator, a discharge port of slurry provided in the stator, and separator disposed near the discharge port for separating medium from the slurry, wherein a screen is provided in the mill bottom, and the product slurry remaining in the mill after grinding is discharged and recovered through the screen by feeding compressed gas from above the mill.

2. A grinding method in a method of grinding raw slurry by a wet agitating ball mill comprising a stator to be filled with medium, a rotor affixed to a shaft rotated and driven by a driving device such as motor, a feed port of raw slurry provided in the stator, a discharge port of slurry provided in the stator, and separator disposed near the discharge port for separating medium from the slurry, wherein the stator is filled with medium by 80 to 90%.

3. A grinding method of claim 2, wherein a vertical mill is used.

4. A wet agitating ball mill comprising a cylindrical stator, a feed port of slurry provided at one end of the stator, a discharge port of slurry provided at other end of the stator, a rotor of pin, disk or annular type for agitating and mixing the medium loaded in the stator and the slurry supplied from the feed port, and a separator of impeller type linked to the discharge port and rotating together with the rotor or rotating independently of the rotor to separate the medium and slurry by the action of centrifugal force and discharge the slurry from the discharge port, wherein the axial center of the shaft for rotating and driving the separator is a hollow discharge port communicating with the discharge port.

5. A wet agitating ball mill of claim 4, wherein it is a vertical type, and the discharge port is provided at the mill upper end.

6. A wet agitating ball mill of claim 5, wherein the feed port is provided in the mill bottom, and is composed of a valve seat, and a valve body of V-form, trapezoid or cone fitted elevatably to the valve seat and contacting linearly with the edge of the valve seat.

7. A wet agitating ball mill of claim 6, wherein the valve body is vibrated vertically by vibrating means.

8. A wet agitating ball mill of claim 4, wherein a screen for separating medium and slurry and a slurry take-out port are provided in the bottom.

9. A vertical type wet agitating ball mill comprising a cylindrical vertical stator, a feed port of product slurry provided in the bottom of the stator, a discharge port of slurry provided at the upper end of the stator, a shaft pivoted on the upper end of the

stator and rotated and driven by driving means  
such as motor, a rotor of pin, disk or annular type  
fixed on the shaft for agitating and mixing the  
medium loaded in the stator and the slurry supplied  
from the feed port, a separator disposed near the  
discharge port for separating medium from the  
slurry, and a mechanical seal provided in the bear-  
ing unit for supporting the shaft at the stator upper  
end, wherein a taper notch expanding downward is  
formed at the lower side of an annular groove to  
which an O-ring contacting with the mating ring of  
the mechanical seal is fitted.

10. A wet agitating ball mill comprising a stator to be  
filled with medium, a rotor affixed to a shaft rotated  
and driven by a driving device such as motor, a feed  
port of raw slurry provided in the stator, a discharge  
port of slurry provided in the stator, and separator  
disposed near the discharge port for separating  
medium from the slurry, wherein the separator is  
composed of two disks having a fitting groove of a  
blade in the confronting inner sides, a blade inter-  
posed between the disks by fitting to the fitting  
groove, and support means for supposing the disks  
having the blade placed therein from both sides.
11. A wet agitating ball mill of claim 10, wherein the  
support means is composed of a step of the shaft  
forming a stepped shaft, and cylindrical pressing  
means for pressing the disks by fitting to the shaft.
